19. ABSTRACT (Continue on reverse if necessary and identify by block number) <i>In this study on atmospheric transmission</i> A study has been performed in which several examples of laser-transmission-calibrated, high-resolution Fourier transform spectrometer (FTS) measurements have been compared with corresponding spectra generated using the FASCOD1C computer model. The experimental data were collected at three coastal sites and one inland site. The measurement path-lengths varied between 4.07 and 6.4 km. Water vapor partial pressures varied between 2.0 and 20.5 torr, partial pressure of water vapor. <i>Infrared</i> Of particular interest in this study is the use of the experimental data in comparison to the water vapor continuum absorption model contained in the FASCOD1C computer model. It was found that the data agree with FASCOD1C predictions for the H <sub>2</sub> O continuum absorption to within the range of uncertainty of the experimental data. The N <sub>2</sub> continuum absorption calculated using FASCOD1C appears to be smaller than that observed and this observation is

thought to be related to an unmodeled temperature dependence in the  $N_2$  continuum absorption.

The experimental high-resolution spectra were compared with calculated continuum absorption by selecting 49 discrete frequencies in the  $1900 - 3200/\text{cm}^{-1}$  region which were minimally influenced by discrete line absorption. Corrections for local line and  $N_2$  and  $CO_2$  continuum absorptions were applied to the experimental data at these 49 frequencies. The data were then compared with  $H_2O$  continuum absorption coefficients calculated using the FASCOD1C model and the 1982 version of the AFGL atmospheric absorption line compilation.

Detailed high-resolution comparisons of the experimental data to FASCODE - generated spectra show excellent agreement in nearly all features throughout the  $1900 - 3200/\text{cm}^{-1}$  spectral region. A notable exception occurs with several weak  $H_2O$  vapor absorption lines occurring between  $2390/\text{cm}^{-1}$  and  $2490 \text{ cm}^{-1}$ . Recommended line strength values for these several lines have been derived from the experimental data and are provided.

Recommendations for further analysis of the data base utilized in the present study and for additional measurements are discussed.

### ACKNOWLEDGEMENTS

A great many individuals contributed to the generation of the data base which is analyzed in the present study. One of the authors (James A. Dowling) was associated with and primarily responsible for the design and deployment of the NRL IMORL facility during the several years that the data base treated herein was generated. Accordingly the following acknowledgements are made.

Many individuals at NRL contributed to this work, especially: T. Cosden - IMORL mechanical design, R. Horton - IMORL optical design, experimental procedures, and data collection and analysis, R. Harris - electronic design, S. Hanley - data collection and analysis, K. Haught - data collection and analysis, D. Garcia - data collection and analysis, P. Livingston - programmatical representation and direction, M. Woytko, C. Gott, J. Cox, W. DeMent, and M. Cochran - IMORL system construction and operation. R. Patten was instrumental in making the NRL IMORL data base available for the present analysis. The IMORL optical system was manufactured by the Muffoletto Optical Co., Baltimore, MD and the FTS system was manufactured by the MIDAC Corporation, Newport Beach, CA.

The work reported herein was sponsored by several DoD agencies. The principals at each of these offices who were instrumental in making this work possible were: NAVSEA PMS-405 - D. Finkleman and M. Hughes, NOSC - Juergen Richter, ASL - G. Hoidale, AFGL - S. Clough, F. Kneizys, and L. Abreu.

The careful and comprehensive work performed in the preparation of the text and numerous figures in this report by Deborah Christmas and Valerie Torres is greatly appreciated.

# 1

## BACKGROUND AND INTRODUCTION

This report describes the analysis of a collection of high-resolution atmospheric transmittance spectra measured during several field experiments performed by the Naval Research Laboratory (NRL) between 1976 and 1979. The data analyzed in the present study consists of 52 individual high-resolution ( $0.0625\text{ cm}^{-1}$ ) spectra for which an absolute-transmission calibration was obtained by nearly-concurrent measurements of deuterium-fluoride (DF) laser transmittance over the same atmospheric path.

The four experiments which yielded the data base analyzed in this study were conducted at three coastal and one inland locations using the NRL Infrared Mobile Optical Radiation Laboratory (IMORL). The IMORL system was an outgrowth of earlier NRL measurement systems used for studies of atmospheric turbulence effects on laser propagation. The system is briefly described in Section 2.

The first NRL experiment in which laser-extinction-calibrated Fourier-transform spectrometer (FTS) data were collected was performed at the Patuxent River Naval Air Station (PRNAS), Maryland in the fall of 1976 [1]. This experiment was followed by a similar, extended measurement program at the Cape Canaveral Air Force Station (CCAFS), Florida during the late-winter and spring of 1977 [2, 3]. Later experiments were performed at the White Sands Missile Range (WSMR), New Mexico [4], and at San Nicolas Island (SNI), California in the spring of 1979 [5].

A principal objective behind the combined use of high-resolution FTS measurements with high-accuracy transmittance values obtained with the IMORL laser transmissometer system

was a measurement of the weak but important absorption in the 3-5  $\mu\text{m}$  atmospheric window contributed by the "so-called" water vapor continuum absorption. Earlier NRL long-path transmittance measurements had shown that the uncertainties associated with the understanding of this continuum absorption represented a major limitation in the ability to correctly predict molecular absorption coefficients for DF laser atmospheric propagation. The high-resolution FTS data provide a direct measure of atmospheric transmittance at spectral locations in the 3-5  $\mu\text{m}$  region where contributions to the absorption coefficient due to strong individual atmospheric absorption lines are minimal or negligible. At these frequencies the residual molecular absorption is due to the water vapor continuum above or the combination of water vapor continuum, the  $\text{N}_2$  continuum and the  $\nu_3$   $\text{CO}_2$  band edge continuum.

Previous analysis and model comparisons have been performed using the large data base of laser transmittance values measured during the several NRL field experiments [1-5]. However, only preliminary comparisons of the NRL high-resolution FTS data to line-by-line high resolution calculations were made [6-7].

The approach used in this study makes use of the high resolution NRL FTS data by comparing measured extinction coefficients, after correction for calculated contributions due to local lines, and due to  $\text{N}_2$  and  $\text{CO}_2$  continua, with calculated water vapor continuum absorption coefficients obtained with the FASCOD1C model [8]. The 1982 AFGL atmospheric absorption line parameters compilation [9] was used together with FASCOD1C for the calculation of local line contributions.

This report is divided into 4 sections, the first being this introduction. In Section 2 the NRL Data base is described. The IMORL apparatus is briefly described in subsection 2.1 and the field measurement locations and meteorological conditions are described in subsection 2.2.

Data analysis, procedures and results are described in Section 3. Subsection 3.1 describes the water vapor continuum analysis and in subsection 3.2 the limited analysis performed comparing individual measured and calculated line absorptions is presented.

Section 4 presents a summary of the conclusions which can be drawn from the analysis and presents a list of recommendations based on the findings in this study.

**THE NRL HIGH-RESOLUTION ATMOSPHERIC TRANSMISSION DATA BASE****2.1 EXPERIMENTAL APPARATUS**

The Infrared Mobile Optical Radiation Laboratory (IMORL) was developed at NRL as a field laboratory for precision atmospheric propagation measurements. Detailed descriptions of the electro-optical instrumentation contained in this facility are presented in References 10 and 11. The essential features of this system are briefly described below to provide the reader with an orientation regarding the high-resolution FTS data base analyzed in this report.

The IMORL system was used extensively to collect laser-calibrated high-resolution atmospheric transmission spectra. The system included several infrared laser and blackbody sources, large, stable telescope optics, a Fourier transform spectrometer (FTS) system, and various support equipment, all of which were transported in and operated from several large semi-trailers. The usual measurement configuration consisted of an optical transmitter trailer housing HeNe, Nd-YAG, DF, CO, and CO<sub>2</sub> single-line, cw laser sources, relay optics, and a large, stably-mounted and precisely-pointed 91 cm aperture, f/35 Cassegrainian collimating telescope. The small cw, combustion-driven DF laser used for much of the laser extinction work required a large (755 l/s) vacuum system for operation. This pump was housed in a separate trailer; a 20 cm diameter vacuum line was installed between the transmitter and vacuum pump trailers once the two trailers were properly located at a measurement site. Two additional trailers contained office space, meteorological signal processing and recording electronics, and bottled

gases and other consumable supplies used during the course of an experiment.

The FTS system and apparatus used for laser extinction measurements were housed in a receiver trailer containing a 120 cm aperture, f/5 newtonian telescope. The large receiver telescope aperture insured that the entire laser beam used during long path extinction measurements could be collected, thereby providing reliable absolute transmission calibrations for the FTS measurements. High resolution transmission spectra were taken by substituting a 1300 K blackbody source for the laser source in the transmitter optical system and adjusting the receiver optical system so as to couple the FTS system to the 120 cm collecting telescope. Repeated calibrations and extensive experience with the measurement system in field experiments demonstrated that absolute transmission could be reliably measured for long atmospheric paths with an uncertainty less than  $\pm 3\%$ .

Figure 1 is a photograph of the transmitter station taken during the experiment at CCAFS. From left to right in the figure can be seen an NRL aerosol-micrometeorological measurement van, the IMORL vacuum pump trailer, optical transmitter trailer (the 91 cm aperture telescope mirror and telescope frame may be seen through the open doors), and the office trailer.

Figure 2 is a schematic depicting the experimental arrangement used for laser extinction measurements. The output beam from any of the several laser sources used was first collimated by auxiliary optics to a diameter of approximately 18 mm. The beam was then focused via the off-axis parabolic mirror shown in the upper left of Figure 2 and then diverged to fill the 91 cm transmitter telescope aperture. A 37 Hz, 50% duty cycle chopper modulated the beam near the focus formed by the off-axis parabola. The

FIGURE 1. NRL IMORL TRANSMITTER STATION DURING THE CCAFS EXPERIMENT.

FIGURE 2. NRL IMORL LASER EXTINCTION MEASUREMENT SCHEMATIC.

beam was alternately transmitted through the telescope and reflected onto the stationary detector as shown. The mobile detector shown in Figure 2 was placed in the "XMTR" position for calibration measurements in which the relative response of the two detectors was measured. The mobile detector was then placed near the focus of the 120 cm aperture receiver telescope for a) calibrations of the large telescope optical efficiency or b) long path extinction measurements. The calibration measurements were carried out with the transmitter and receiver trailers immediately opposite one another, i.e., for zero atmospheric path. When the trailers were separated for long path measurements the two types of calibration data were then used to determine absolute atmospheric transmittance for the several laser lines studied. As shown in Figure 2, the signal produced by the mobile detector in the receiver trailer at one end of the measurement path was relayed to the transmitter by means of a pulse-rate-modulated (PRM) GaAs-laser-based data link. This signal, proportional to laser power at the receiver, was connected to the numerator input of a special purpose analog ratiometer, [11]. The stationary detector signal, proportional to the transmitted laser power was connected to the denominator input of the ratiometer. Thus, a real time measure of transmittance for the laser line being studied was available at the transmitter site. The ratiometer reading was corrected for the relative response of the two detectors for that laser line (monitored daily) and the efficiency of the large optical elements beyond the chopper in order to obtain absolute transmission readings. As shown in Figure 2, the voltage-controlled oscillator (VCO) and frequency-to-voltage converter (FVC) used with the GaAs data link were also connected in the numerator circuit of the ratiometer when the mobile detector was used in the "XMTR"

position, so that their combined transfer function was normalized out of the final extinction ratio.

Figure 3 is a schematic diagram showing the configuration of the transmitter and receiver optical systems used for FTS measurements.

Local meteorological measurements were usually performed at each end of the measurement path. Absolute humidity, air temperature and pressure, and wind conditions were monitored in order to document local conditions during a series of measurements, to provide assurance that uniform environmental conditions existed along the measurement path, and that these conditions remained constant during a complete measurement cycle. The period required to make both laser extinction and FTS measurements, in turn, was typically about one hour. Measurements using an aerosol spectrometer system in the NRL aerosol van were performed during some of the measurements analyzed in this report. Infrared aerosol extinction estimates based on Mie scattering calculations, utilizing the measured particle distributions, have shown good agreement with results derived from infrared extinction measurements at Nd-YAG and DF laser wavelengths. This agreement was obtained during earlier experiments [12] conducted at an inland location, removed from the local effects of surf, etc., which existed during three of the four experiments addressed in this report. However, for the measurements discussed in this report, poor agreement between aerosol-analyzer-derived extinction coefficients and those determined from long-path optical measurements was generally observed.

FIGURE 3. OPTICAL SCHEMATIC DIAGRAM FOR FTS MEASUREMENTS.

## 2.2 FIELD MEASUREMENT LOCATIONS AND METEOROLOGICAL CONDITIONS

### 2.2.1 PATUXENT RIVER NAVAL AIR STATION

The 5.12 km overwater path used for the PRNAS measurements is shown in Figure 4. The IMORL transmitter station was located at the south end of the PRNAS at location A in the figure. The receiver station was placed at location B in the figure which is a small radar installation used to support operations at the PRNAS.

All of the PRNAS spectra analyzed in this report were measured during mid-November 1976 except for the one designated PR024 which was measured on 24 September. The meteorological conditions occurring on September 24 included moderate values of air temperature and absolute humidity of  $18.3^{\circ}\text{C}$  and 12.0 torr water vapor partial pressure ( $\text{ppH}_2\text{O}$ ), respectively. The remainder of the spectra were collected between 8 and 19 November 1976, during conditions of relatively low air temperatures ( $-1.7$  to  $8.5^{\circ}\text{C}$ ) except for 19 November when the air temperature was  $17.5^{\circ}\text{C}$ . The absolute humidity variations encountered during November were confined to relatively low values between 2.5 and 3.0 torr  $\text{ppH}_2\text{O}$ .

Table 1 presents summary of the meteorological conditions occurring during the PRNAS measurements. Also included in Table 1 is information relating to measured and/or derived aerosol extinction values at  $0.5\ \mu\text{m}$  and  $3.8\ \mu\text{m}$ . For the PRNAS data, the aerosol extinction coefficients at  $0.55\ \mu\text{m}$  were obtained from visibility measurements performed for times close to the laser extinction measurement times. The corresponding values for  $3.8\ \mu\text{m}$  were obtained from the  $0.55\ \mu\text{m}$  values using the wavelength scaling procedure described in subsection 3.1.1.2. The four right-most columns

<sup>+</sup>Meteorological data records were obtained for these quantities from the Naval Ocean Command (NAVOCOM) weather station at PRNAS. In cases where both NRL and NAVCOM data were available and differed, the average value of the two data items was used.

of Table 1 contain information relating to the availability of previously unpublished tabulations of values for local transmission maxima in the  $2400 - 3200 \text{ cm}^{-1}$  region for the spectra, the availability of a high resolution digital tape file for the spectrum, and absolute-transmission-normalization correction factors and fitting errors derived as part of the present study. The latter two quantities are discussed in Section 3.

### **2.2.2 CAPE CANAVERAL AIR FORCE STATION**

The location of the 5.08 km path used for the CCAFS measurements described in this report is shown in Figure 5. The optical transmitter station was located at the shore end of Camera Rd. "A" and the receiver station was located at the shore end of South Patrol Rd. as shown in the figure.

One of the principal advantages of the CCAFS site for laser propagation and high-resolution transmission studies during the late-winter and spring seasons is the wide variation in absolute humidity which can be expected to occur at that location. Since water vapor in its two most abundant isotopic forms ( $\text{H}_2\text{O}$  and  $\text{HDO}$ ) is a principal molecular absorber at  $\text{DF}$ ,  $\text{CO}$  and  $\text{CO}_2$  laser wavelengths, validation of molecular absorption models is greatly facilitated by experimental data collected under such widely ranging conditions, particularly when associated meteorological changes in aerosol composition and concentration and air temperature are relatively small by comparison. The variation of meteorological conditions encountered during the NRL 1977 CCAFS experiment proved to be quite useful in meeting the experimental objectives; a range of absolute humidity between a moderately low value of 6 torr  $\text{ppH}_2\text{O}$  to over 20 torr  $\text{ppH}_2\text{O}$  was observed. The wind conditions encountered during the

FIGURE 5. CCAFS ATMOSPHERIC TRANSMISSION TEST SITE.

experiment included winds originating from both overwater and overland directions, giving rise to both maritime-like and predominately continental atmospheric aerosol compositions, and a range of visibilities between 10 and 50 km. Table 2 contains a summary of the meteorological conditions encountered during the experiment. The maximum and minimum values observed for several relevant meteorological parameters are listed in part 1 of the table while part 2 contains a daily summary including the nature of the wind conditions (absolute wind direction, direction relative to the optical propagation path, and wind speed) along with the absolute humidity, air temperature, visibility, and insolation recorded during each of the transmission measurements periods. Apparent aerosol extinction (AAE) values (measured extinction minus calculated molecular absorption) for the four laser wavelength regions studied are also included in section 2 of the table.

The symbol "~" used in several places in Table 2 is intended to indicate average or approximate values for the corresponding entry as a result of: a) forming averages based on visual inspection of the appropriate individual values, or b) estimating a typical average value for a parameter which changed in a systematic manner during the course of an experiment period; e.g., insolation typically varied from about  $1.2 \text{ w/cm}^2$  around 1300 hours to about  $0.80 \text{ w/cm}^2$  near 1500 hours, therefore an entry of  $1.00 \text{ w/cm}^2$  is used as an average value.

Some general observations can be made upon examination of Table 2. During the first of the three periods when long-path transmission measurements were performed (March 2 through 15, 1977) three distinct frontal passage situations were encountered, occurring on 2, 8 and 14 March. The frontal passages were typified by overland wind directions,

relatively low values of absolute humidity and high visibilities. (Refer to Figure 5 for wind direction information). The four days occurring during the middle portion of this period (March 9 through 12, prior to a cold front passage on 14 March) exhibited a weather pattern marked by winds moving from NE to SE, along with increasing absolute humidity and decreasing visibility. It is interesting to note that the air temperature decreases lag the onset of frontal passages by as much as one day; note the drop in air temperature on 8 March and the less dramatic drop on 15 March after several days of systematically increasing temperatures.

The second and third long-path measurement periods (31 March through 5 April and 16 May through 25 May, respectively) presented more static weather situations with predominately overwater wind conditions except for 5 April when another frontal passage occurred. During the second period generally high water vapor conditions (18 torr  $\text{ppH}_2\text{O}$ ), high air temperatures ( $24^\circ\text{C}$ ) and moderate visibilities (14 to 30 km) accompanied the steady and moderate ( $\sim 5$  m/s) overwater winds which were primarily perpendicular to the optical path (see Figure 5). Measurements performed during this period should be quite representative of overwater propagation conditions since the conditions along the propagation path would be expected to be more nearly uniform with a wind direction near-normal to the optical path. The third experimental period between 16 and 25 May inclusive exhibited exclusively overwater wind conditions with intermediate to high values of absolute humidity, increasing air temperatures and moderate to high visibilities. On all days during the third measurement period, with the exception of 17 May, wind directions were nearly perpendicular to the optical path and varied between

ENE and SSW. These general observations are useful when interpreting the transmission measurements analyzed in this report.

Table 3 contains the information pertinent to the CCAFS spectra analogous to that presented in Table 1 for the PRNAS data.

### 2.2.3 SAN NICOLAS ISLAND

The 4.07 km overwater path used in the SNI measurements is shown in Figure 6. The NRL IMORL transmitter station was located at site A and the receiver was located at site C in the figure. The path is located along the northern shoreline of SNI.

The meteorological conditions occurring during the SNI experimental period were quite constant when compared with the PRNAS and especially the CCAFS data. A small variation of less than 1 torr in absolute humidity (8.1 to 8.9 torr  $\text{ppH}_2\text{O}$ ) and of slightly more than one degree Celsius in air temperature (10.1 to 11.7°C) characterize the atmospheric conditions occurring during the times that laser transmission and FTS measurements were made. In general, moderately high windspeeds between 5.7 and 11.5 m/s, accompanied by moderate visibilities, occurred during the measurement period. The moderately high windspeeds and the proximity of shoals upwind of the propagation path are viewed as contributing to the generation of proportionately larger aerosol extinction coefficients in the 3-5  $\mu\text{m}$  region than in the case of the CCAFS or PRNAS data. The relatively isolated location of SNI in the open ocean is expected to result in the presence of a more maritime-like aerosol with a proportionately larger number of larger particles, resulting from condensation on wave-generated salt-particle nuclei. In these cases aerosol extinction coefficients are expected to

be more nearly comparable for visible and infrared wavelengths than in the case of a continental aerosol where the particulate size distribution contains relatively fewer large particles.

Table 4 contains a summary of the information pertaining to the SNI spectra that was presented earlier for the PRNAS and CCAFS data in Tables 1 and 2.

#### **2.2.4 WHITE SANDS MISSILE RANGE**

The measurement sites used for the WSMR/ASL experiment are shown in Figure 7. The IMORL transmitter station was located on an elevated berm approximately 5 m above the desert floor near WSMR Arky site. The receiver station was located on a berm used for photographic data collection at the WSMR PAT site and was approximately 8 m above the desert floor. The propagation path of 6.4 km extended in a nearly north-south direction as shown in Figure 7.

The meteorological conditions occurring during the WSMR experiment are characterized by moderate temperatures (15.6 to 21.7°C), low absolute humidities ranging between 2.0 and 4.5 torr ppH<sub>2</sub>O and very high visibilities, varying between 46 and 168 km.

A summary of the meteorological conditions and normalization parameters describing the WSMR FTS data is presented in Table 5.

### **3 DATA ANALYSIS**

#### **3.1 WATER VAPOR CONTINUUM ABSORPTION ANALYSIS**

##### **3.1.1 EVALUATION OF ABSOLUTE-TRANSMISSION NORMALIZATION UNCERTAINTIES**

The procedures used in deriving absolute transmission calibrations for the NRL FTS spectra involved the initial generation of a relative transmission spectrum, followed by absolute-transmission normalization of this spectrum using the measured absolute transmittance values obtained from a set of DF laser transmittance measurements.

By ratioing the long-path spectra to local source spectra, the source, beamsplitter, and detector spectral response functions were removed from the resulting spectra. The ratioed spectra were then converted from relative to absolute transmission by determining the scale factor needed to convert the relative transmission value of a spectrum at a particular laser frequency to the absolute transmission value obtained by means of an independent, long-path laser extinction measurement.

Detailed numerical examples showing the application of these procedures to the normalization of the WSMR and SNI data are provided in References 4 and 5, respectively. During the course of the detailed procedures used in the normalization of the WSMR and SNI spectra, the selection of a subset of the several available DF laser transmittance measurements was made to exclude measurements for laser lines located in close proximity to strong atmospheric absorption lines. The uncertainty associated with using a measured transmittance value for such a line to normalize an FTS spectrum was found to be substantially larger (several percent uncertainty) than that associated with the use of a

line well isolated from the effects of strong local lines. Consequently, a re-evaluation of the atmospheric-transmission-normalization of the PRNAS and CCAFS spectra was performed, excluding such lines in question (e.g. the P2-10 DF laser line). The results of this re-normalization are shown under the heading "absolute normalization correction factor" in Tables 1, 2, 4, and 5. As can be seen in the tables, the absolute-transmission correction factors thus obtained differ from unity by  $\pm 1\%$  and are consequently not significant within the overall experimental uncertainty in the measured data. These correction factors do not apply to the WSMR and SN1 data which were originally normalized using the selected subset of laser line measurements. The right-most columns in Tables 1, 2, 4, and 5 list the RMS deviations of the differences between measured individual laser transmittance values and the absolute transmittance value of a resultant normalized FTS spectrum at the frequency of that laser line (actually the transmittance values at the two spectrum sample locations that bracket the position of the laser line frequency). These RMS deviations (labeled fitting errors in the tables) provide a measure of the overall quality of fit or normalization uncertainty, as well as an indirect measure of spectral signal to noise ratio. For the best examples (several CCAFS spectra) these quantities are  $< \pm 1\%$  in absolute transmittance. The "worst case" examples are seen to be  $\sim \pm 5\%$  in absolute transmittance. It is felt that the strength of atmospheric turbulence along the measurement path occurring during both the laser and FTS transmittance measurements is a primary factor in determining the magnitude of the fitting errors listed in the tables. The smaller numerical values correspond to data of higher quality and greater reliability.

### 3.1.2 CORRECTIONS TO THE EXPERIMENTAL DATA

In the 3-5  $\mu\text{m}$  window considered here, three phenomena play major roles in the reduction of atmospheric transmission data, namely aerosol extinction, molecular absorption lines, and molecular continuum absorption. Multiple-scattering effects due to aerosols are not significant in the data examined below, since the aerosol extinction coefficients are typically small ( $< 0.2 \text{ km}^{-1}$ ). Modification of apparent transmission by thermal emission is also neglected in the following analysis since the laser source used in the measurements was modulated at the source location. Unmodulated emission from the intervening path was therefore not detected in the laser extinction measurements. Independent FTS measurements of the optical path emission (using the same configuration as used during laser and FTS transmission measurements, only with the blackbody source not operating) showed that path emission in the 3-5  $\mu\text{m}$  region was negligible compared with the blackbody source signal.

The comparisons of measured FTS data with water continuum absorption calculations performed using the FASCODE model which are presented below are based on a correction of the measured data for local absorption line,  $\text{CO}_2$  and  $\text{N}_2$  continuum, and aerosol scattering effects. The optical depth at selected frequencies arising from the first two types of corrections was calculated and subtracted from the optical depths obtained from the measured data. Aerosol scattering contributions to the optical depths obtained from the transmission data are not readily discernible. In most cases (for data other than selected CCAFS spectra) reliable, independent aerosol extinction values are not available, consequently no well-defined distinction between water continuum absorption and aerosol scattering contributions to the measured optical depth can be made. In these cases the

"shape" of the water vapor continuum absorption coefficient can be examined by comparisons with comparable values calculated using the FASCODE model. This approach relies upon the assumption that the aerosol contribution to the measured optical depth can be obtained from the difference between the measured optical depth, corrected for local line and  $N_2$  and  $CO_2$  continua contributions, and the calculated optical depth due to water vapor continuum absorption obtained using FASCODE. That is, the magnitude of the calculated water vapor continuum absorption is assumed to be correct at some frequency and the difference between it and the measured optical depth (appropriately corrected for molecular absorption) is the aerosol extinction component at that frequency. This aerosol component, with appropriate scaling in wavelength, can then be subtracted from the measured data throughout the  $1900 - 3100 \text{ cm}^{-1}$  region and any systematic differences between the measured optical depth and that calculated using FASCODE can be determined.

Detailed information describing the calculated local line and  $N_2$  and  $CO_2$  continuum corrections and the corrections for aerosol extinction applied to the measured data is presented in the following two subsections.

#### 3.1.2.1 Corrections for Local Line and for $CO_2$ and $N_2$ Continuum Contributions

The water vapor continuum is best observed at wavenumbers where molecular line contributions to total absorption are minimized. A set of 49 such wavenumbers in the  $3-5 \mu\text{m}$  band was chosen for this study. Nevertheless, the effects of wings of molecular lines local to the selected wavenumbers is frequently strong and must be evaluated.

The local line absorption at a frequency  $\nu_0$  is defined as the absorption due to all the lines whose centers are

within some distance  $\Delta\nu$  from  $\nu_0$ . The difference between the measured and the local line absorptions is the "continuum". The magnitude of the continuum depends upon the interval  $\Delta\nu$ . For the calculations performed in this study  $\Delta\nu = 25 \text{ cm}^{-1}$  around the line frequency  $\nu_0$ . The local line contributions were computed with the aid of FASCOD1C, in a mode where continuum effects were excluded. The results of this computation were considered reasonably accurate, since much theoretical and experimental work has been made in the description of line shapes and strengths in this wavenumber region.

The local line contributions were calculated using the computer program FASCOD1C [8] and the 1982 version of the AFGL Atmospheric Line Parameters Compilation [9]. This program uses a Voigt line shape for all molecules except  $\text{CO}_2$  for which an exponential-tailed line shape described in [13] is used. These calculations are concerned with the regions between lines and away from line centers. In these regions the Voigt line shape is essentially the Lorentz line shape.

A final phenomenon treated in this work is the molecular continuum absorption due to  $\text{N}_2$  and  $\text{CO}_2$ . These continua are especially prominent in the  $2200\text{--}2500 \text{ cm}^{-1}$  wavenumber region, as is the  $\nu_3$   $\text{CO}_2$  band. In recognition of the strong absorption band and continuum, no sampling points were situated in the  $2223 - 2400 \text{ cm}^{-1}$  wavenumber interval. The  $\text{N}_2$  and  $\text{CO}_2$  continuum models of FASCOD1C were utilized to estimate continuum absorption at sampling points in the vicinity of the  $\nu_3$  band.

The absorption coefficient due to the water vapor continuum  $\alpha_{wc}$  is simply the observed total extinction coefficient  $\epsilon$  minus the individual coefficients due to other effects:

$$\alpha_{wc} = \epsilon - (\alpha_{LL} + \alpha_{CON} - \sigma_{AER}), \quad (1)$$

where  $\alpha_{LL}$  is the absorption coefficient due to local lines,  $\alpha_{AER}$  is the aerosol extinction coefficient at 3.8  $\mu\text{m}$ , and  $\alpha_{CON}$  is the  $\text{N}_2$  and  $\text{CO}_2$  continuum absorption coefficient (all dimensions are in  $\text{km}^{-1}$ ).

For this analysis, 49 wavenumbers were chosen for which the absorption is a local minimum; these wavenumbers are listed in Table 6. There are 16 points between 1930 and 2224  $\text{cm}^{-1}$ , and 33 points between 2400 and 3059  $\text{cm}^{-1}$ , spaced approximately every 20  $\text{cm}^{-1}$ . Figure 8 shows the location of these points on a plot of the measured spectrum ASL06RN. Figure 9 shows the 2  $\text{cm}^{-1}$  wide region around each point and includes both the measured spectrum ASL06RN plus calculations of only the local line contribution for 2.5, 5.0, 10.0, and 20.0 torr of water vapor. These plots demonstrate that the chosen points are points of locally minimum absorption and also minimum local line contributions. The measured spectrum shows that there are no significant lines at the chosen wavenumbers which are missing from the AFGL line tape.

It should be noted that the resolution of the measured transmittances is limited by the instrument function. Since the measured spectra are unapodized, the instrument function has the form  $\sin v/v$  with a half width at half height of about 0.019  $\text{cm}^{-1}$  (and a full width at the base of 0.0625  $\text{cm}^{-1}$ ). The halfwidths (half width at half height) of the absorption lines in this region are about 0.1  $\text{cm}^{-1}$  on the average but for some water lines they are as small as 0.01  $\text{cm}^{-1}$ . The effect of the instrument function width is to degrade the spectrum around the center of lines, increasing the measured width of the lines and decreasing the measured absorption at the line center. Therefore it is not strictly proper to plot the logarithm of the measured transmittances on an optical depth scale, as in Figure 9. How-

ever, we are concerned here with the regions between absorption lines where the effect of the instrument function is negligible.

Table 7 lists the meteorological conditions corresponding to the measured spectra used in this study. For each of these spectra, the measured optical depth ( $= -\ln T$ ) was corrected for aerosol, local line, and  $N_2$  and  $CO_2$  continuum contributions. The differences are then the measured continuum values. Table 8 lists 19 sets of conditions for the local line and  $N_2$  and  $CO_2$  continuum calculations along with the measured spectra associated with each calculation. Table 9 gives the volume mixing ratios used to calculate the path-integrated amounts for the gases other than water vapor. A single local line calculation was used for spectra with similar water vapor partial pressures. No aerosol extinction was included in the calculation. The local line contributions were calculated at approximately every  $0.05 \text{ cm}^{-1}$  which, in general, did not match exactly the wavenumbers in Table 6. For each wavenumber in Table 6, the nearest three calculated points were averaged. Similarly, the measured spectra are tabulated at intervals of about  $0.06 \text{ cm}^{-1}$ . For all but the Cape Canaveral spectra, the three measured points nearest to the wavenumbers in Table 6 were used; for the Cape Canaveral spectra, only the nearest point was used. The results of the calculated values for the local line, and  $N_2$  and  $CO_2$  continuum contributions for each of the frequencies listed in Table 6 and for each of the 19 cases listed in Table 8 are tabulated in appendices B and C, respectively.

#### 3.1.2.2 Corrections for Aerosol Scattering

Attenuation due to aerosol extinction is not a well-defined quantity in the available data, for various reasons.

Aerosol size distribution data obtained at the SNI site, for example, were probably dominated by surf-generated aerosols for most observed wind directions [5]. Under wind conditions where the aerosol sampling instrumentation at SNI was subjected to strong local surf effects and the majority of the 4.07 km over-water transmission path was not, the optical depth along the transmission path can be grossly overestimated. Sample calculations (which assume a particle size distribution homogeneous over the transmission path) confirm this point, yielding optical depths (due solely to aerosol extinction) which frequently exceed the observed optical depth. The aerosol extinction coefficient for the SNI data was therefore estimated using the Navy Aerosol Model [14]. This empirically-based model considers such factors as relative humidity, wind speed, visibility at 0.55  $\mu\text{m}$ , and airmass type in the specification of an aerosol extinction coefficient at a particular wavelength. The SNI meteorological data (see Table 3) specify all necessary parameters, with the exception of airmass type.

Airmass type (open oceanic, coastal, continental) happens to correlate very well with the level of atmospheric radon (which is produced by the decay of radium in crustal rock formations). Reference 14 gives an expression for an integer parameter P (which varies between 1 and 10) descriptive of the airmass type:

$$P = \text{INT} (R_n/4) + 1 \quad (2)$$

where INT ( ) is a function which truncates its argument to the next lowest integer and  $R_n$  is the decay rate activity of atmospheric radon (expressed in picocuries per cubic meter). An oceanic airmass typically has  $P = 1$  and a continental airmass usually has  $P = 10$ . Atmospheric radon measurements

were taken concurrently with the transmission spectra, [15,16], thus completing the essential input for the aerosol model. As expected, the aerosol extinction predicted by the model was frequently quite lower than that inferred from surf-influenced particle measurements for the SNI data.

For the other three experimental sites PRNAS, CCAFS, and WSMR, extinction coefficients in the 3-5  $\mu\text{m}$  region were estimated by scaling values obtained in the photopic region from available visibility data, except for selected CCAFS data where Nd-YAG laser transmittance measurements were available.

The aerosol extinction coefficient for visible wavelengths is related to the visual range  $V$  by Koschmeider's formula:

$$\sigma_{0.55} = 3.912/V. \quad (3)$$

Incorporating a small correction for molecular scattering, the relationship becomes:

$$\sigma_{0.55} = 3.912/V - .0123. \quad (4)$$

For any given aerosol of known size distribution and composition, the relationship between extinction coefficients at various wavelengths remains constant. Therefore, we can perform the simple scaling:

$$\sigma_{\text{AER}}(\lambda, V) = \frac{(\frac{3.912}{V} - .0123) \sigma_{\text{AER}}(\lambda, V_0)}{\sigma_{\text{AER}}(0.55 \mu\text{m}, V_0)} \quad (5)$$

Reference 17 provides the necessary parameters to apply this scaling formula for the aerosol types defined by Shettle and Fenn. This formula does not represent what actually happens in the atmosphere when the visibility changes. While the formula implies only a change in the aerosol number density, usually there is also a change in both the composition of the aerosol and the particle size distribution. This is because the change in visibility is often accompanied by a change in the relative humidity.

Attempts were made to minimize the impact of the uncertainties in the value of the aerosol extinction component to the total optical depth by excluding (where possible) those spectra obtained under conditions where the visual range was less than 20 km.

Attempts to estimate the aerosol extinction component of the total optical depth utilizing concurrent aerosol spectrometer measurements (CCAFS and SNI data) and/or concurrent visibility data (all data sets) did not yield consistent values for the observed water continuum absorption coefficients, when aerosol optical depths were subtracted from the measured total optical depth. Therefore, an alternate approach was used in the evaluation of the aerosol component in the experimental data. This latter approach assumes that magnitude of the calculated water continuum absorption coefficient is correct at a certain frequency and that the aerosol contribution can be estimated from the difference between the measured extinction and the calculated water continuum absorption coefficient at that frequency.

A cursory study of the FASCOD1C-computed local line and continuum contributions indicates that these factors make a minimum contribution to the total extinction at the  $2700.720 \text{ cm}^{-1}$  sample point. Under the assumption that the

local line and continuum results at this sample point are correct, one may subtract the computed results from the observed optical depth  $\tau_{OBS}(\nu_O)$  at  $2700.720 \text{ cm}^{-1}$  to get an aerosol extinction coefficient:

$$\sigma_{AER}(\nu_O) = [\tau_{OBS}(\nu_O) - [\tau_{LL}(\nu_O) + \tau_{CONT}(\nu_O)]]/L_{PATH} \quad (6)$$

where  $\nu_O = 2700.72 \text{ cm}^{-1}$ , and  $L_{PATH}$  = total path length.

Equation 6 establishes the aerosol extinction coefficient at a particular wavenumber. The relatively large wavenumber range covered by the sampling points in this study makes the assumption of a wavenumber-invariant aerosol extinction coefficient somewhat tenuous. Examination of Figure 10 (which is a plot of maritime aerosol extinction as a function of wavelength presented in Figure 17 from Reference 17) indicates three things of interest here:

- (a) the aerosol extinction curve is relatively free of kinks or strong curvature in the  $3\text{-}5 \mu\text{m}$  interval
- (b) the linearity of the curve in the  $3\text{-}5 \mu\text{m}$  interval on the log-log plot means that fits of the form  $\sigma(\nu) = C\nu^{-n}$  or  $\sigma(\lambda) = C\lambda^{+n}$  can be made ( $n < 0$ )
- (c) the slope of the curve on the log-log plot does not appear to be strongly dependent upon relative humidity in the 50% - 95% range.

A straight line was fit to the 70% RH curve of Figure 10 and extended to the left and right boundaries of the plot frame. The (x, y) values at the two intersections give the value of n:

$$n = \frac{\ln y_2 - \ln y_1}{\ln x_2 - \ln x_1} = -0.968 \quad (7)$$

FIGURE 10. VOLUME EXTINCTION AS A FUNCTION OF RELATIVE HUMIDITY FOR A MARITIME AEROSOL WHOSE TOTAL NUMBER DENSITY IS FIXED AT 4,000 cm<sup>-3</sup> [17].

thus, for the wavenumber ( $\nu$ ) domain, one obtains

$$\sigma_{\text{AER}}(\nu) = C\nu^{+0.968}, \quad (8)$$

where

$$C = \sigma_{\text{AER}}(\nu_o) \nu_o^{-0.968} \quad (9)$$

The value of  $C$  is the quantity determined for each observed spectrum, using the value for  $\sigma_{\text{AER}}(\nu_o)$  given by Equation 6.

Plots showing the results of this fitting process for all of the spectra studied are contained in the following section. The relative results (how well the forms of the "observed" and theoretical  $\text{H}_2\text{O}$  continuum curves overlap) appear to be quite acceptable. The absolute fit of the continuum is only approximate, since the aerosol extinction uncertainties are poorly known.

A subset of the CCAFS spectra is amenable to further analysis regarding the magnitude of the water vapor continuum absorption coefficient at the  $2700.720 \text{ cm}^{-1}$  point. For certain of the CCAFS spectra, measured Nd-YAG laser transmittances at  $1.06 \text{ }\mu\text{m}$  are available [2,3]. Table 10 provides a listing of the Nd-YAG transmittance measurement times and extinction coefficients together with the identifications and measurement times for the FTS spectra and the times of the DF laser transmittance measurements used for normalization of the FTS spectra.

Using the curves shown in Figure 10, the ratio of the aerosol scattering coefficient at  $3.7027 \text{ }\mu\text{m}$ , ( $2700.720 \text{ cm}^{-1}$ ), to that at  $1.06 \text{ }\mu\text{m}$  can be estimated for various values of relative humidity. Figure 11 shows the dependence of the  $\sigma_{3.7}/\sigma_{1.06}$  ratio upon relative humidity which was derived from the curves shown in Figure 10. Using the mea-

FIGURE 11. RATIO OF  $\sigma_{3.7} / \sigma_{1.06}$  FOR MARITIME AEROSOL FOR VARIOUS VALUES OF R.H. DERIVED FROM REFERENCE 17.

sured values of  $\sigma_{1.06}$  given in Table 10 and the scaling factor shown in Figure 11, aerosol contributions independent of the measured FTS extinction were obtained for the several CCAFS spectra listed in Table 10.

When these values of  $\sigma_{\text{AER}}$  at  $2700.720 \text{ cm}^{-1}$  are substituted into equation 1 independent values for  $\alpha_{\text{WC}}$  can be obtained. Plots showing comparisons of the appropriately corrected measured data for the several CCAFS spectra listed in Table 10 to FASCOD water vapor continuum absorption calculations are shown in and discussed in Figure 16, subsection 3.1.4.

### **3.1.3 GENERATION OF WATER VAPOR ABSORPTION COEFFICIENTS FROM FASCOD1C**

As configured in its public distribution form, the FASCOD1C code package does not permit direct access to individual  $\text{H}_2\text{O}$ ,  $\text{N}_2$ , or  $\text{CO}_2$  continua. That portion of the code responsible for generation of continuum absorption coefficients was extracted and configured to run as a "stand alone" program on a micro-computer. This continuum generation program accepts the following parameters as input: total air pressure, air temperature, column number densities of  $\text{H}_2\text{O}$ ,  $\text{CO}_2$ ,  $\text{O}_3$ ,  $\text{N}_2\text{O}$ ,  $\text{CO}$ ,  $\text{CH}_4$ ,  $\text{O}_2$ , and  $\text{N}_2$ , and the array of wavenumber values at which absorption is to be computed. The output is the optical depth due to water vapor continuum alone or the sum of all continua ( $\text{H}_2\text{O} + \text{N}_2 + \text{CO}_2$ ).

The FASCOD1C local line and continuum computations were carried out for standard conditions which closely approximate those for which the observed transmission spectra were taken. Table 8 indicates the mapping between these standard conditions and specific atmospheric spectra.

given in Table 10 and the scaling factor of the measured FTS extinction were obtained for the several CCAFS spectra listed in Table 10.

When these values of  $\sigma_{AER}$  at  $2700.720 \text{ cm}^{-1}$  are substituted into equation 1 independent values for  $\alpha_{WC}$  can be obtained. Plots showing comparisons of the appropriately corrected measured data for the several CCAFS spectra listed in Table 10 to FASCOD water vapor continuum absorption calculations are shown in and discussed in Figure 16, subsection 3.1.4.

### 3.1.3 GENERATION OF WATER VAPOR ABSORPTION COEFFICIENTS FROM FASCOD1C

As configured in its public distribution form, the FASCOD1C code package does not permit direct access to individual  $\text{H}_2\text{O}$ ,  $\text{N}_2$ , or  $\text{CO}_2$  continua. That portion of the code responsible for generation of continuum absorption coefficients was extracted and configured to run as a "stand alone" program on a micro-computer. This continuum generation program accepts the following parameters as input: total air pressure, air temperature, column number densities of  $\text{H}_2\text{O}$ ,  $\text{CO}_2$ ,  $\text{O}_3$ ,  $\text{N}_2\text{O}$ ,  $\text{CO}$ ,  $\text{CH}_4$ ,  $\text{O}_2$ , and  $\text{N}_2$ , and the array of wavenumber values at which absorption is to be computed. The output is the optical depth due to water vapor continuum alone or the sum of all continua ( $\text{H}_2\text{O} + \text{N}_2 + \text{CO}_2$ ).

The FASCOD1C local line and continuum computations were carried out for standard conditions which closely approximate those for which the observed transmission spectra were taken. Table 8 indicates the mapping between these standard conditions and specific atmospheric spectra.

independent aerosol extinction components could be determined. In Figures 16 (a) through 16 (e) the data shown in Figures 15 (b) through 15 (g) (except 15 (e)), have been replotted, using the scaled Nd-YAG measurements to determine the aerosol extinction at  $2700.270 \text{ cm}^{-1}$ .

Tabular listings of the data shown in Figures 12 through 16 are contained in Appendix A. Included in these tabulations are the water vapor continuum absorption coefficient values calculated using the appropriate FASCODE case and the ratios and differences between each of the measured spectral values and the corresponding calculated values.

The DF laser line transmittance measurements typically used for absolute-transmittance normalization of the FTS spectra span the region between  $2527.391 \text{ cm}^{-1}$  (P2-12 line) and  $2727.309 \text{ cm}^{-1}$  (P2-4 line). This is the case for the ASL and SNI spectra. The PRNAS spectra were normalized using varied sets of DF laser transmittances as shown in Table 11. The CCAFS spectra shown in Figures 15 and 16 were normalized using six DF laser lines between the P2-12 line ( $2527.391 \text{ cm}^{-1}$ ) and the P1-6 line ( $2767.968 \text{ cm}^{-1}$ ).

Several observations can be made upon examination of the plots shown in Figures 12-16 and the corresponding tabulated data presented in Appendix A. Consistently, in all of the data sets, one sees that the experimental data point at  $2223.68 \text{ cm}^{-1}$  shows a considerably larger optical depth than does the FASCODE calculation. The converse is generally true for the data point located at  $2719.28 \text{ cm}^{-1}$ .

An examination of the local line optical depth calculations for these frequencies (shown in Figure 9) shows that they occur in troughs between strong absorption lines. In such situations small registration errors ( $\leq 0.1 \text{ cm}^{-1}$ ) in the experimental wavenumber scale can cause substantial discre-

pancies in the calculated corrections for local line contributions. Further examination of the plots shown in Figure 9 shows that data points located at  $2979.52 \text{ cm}^{-1}$  and  $3020.26 \text{ cm}^{-1}$  also fall into this category. It is not surprising to see the experimental data points corresponding to the four above frequencies deviate from otherwise smooth curves in the plots shown in Figures 13-16.

Additional observations are consistently evident in all of the comparisons shown in Figures 12-16. These include (with respect to the calculated FASCODE results): a) consistently larger measured extinction values for the three frequencies  $2400.00$ ,  $2420.42$ , and  $2440.84 \text{ cm}^{-1}$ , b) consistently lower measured extinction values for the data points between  $1930.30$  and  $2190.95 \text{ cm}^{-1}$ , and c) for those spectra collected during conditions of lower absolute humidity, (ASL and PRNAS) generally a larger measured extinction than the calculated values for  $\nu > 2800 \text{ cm}^{-1}$ .

In comparing the plots with one another one should be mindful of the differences in the ordinate scales for the various plots. The ASL and PRNAS spectra were collected during conditions of low absolute humidity and the water continuum absorption coefficients are correspondingly low, with typical values ranging from  $0.002$  to  $0.009 \text{ km}^{-1}$  at  $2700 \text{ cm}^{-1}$ , except for spectrum PRO24 where the value is  $0.019 \text{ km}^{-1}$ . Small uncertainties in the aerosol component of the total extinction tend to obscure the comparisons shown in Figures 12 and 13 for the ASL and PRNAS data. In general, the magnitude of the calculated water continuum absorption coefficient is comparable to or even smaller than the experimental uncertainty in the measured extinction coefficient corresponding to a  $\pm 3\%$  transmittance measurement uncertainty. The relative uncertainty in extinction,  $d\epsilon/\epsilon$ ,

is related to the relative uncertainty in transmittance  $dT/T$  by the relationship:

$$d\epsilon/\epsilon = - (1/\ln T) dT/T. \quad (10)$$

When the extinction coefficient at  $2700 \text{ cm}^{-1}$ ,  $\epsilon$ , equals  $0.002 \text{ km}^{-1}$  (apart from aerosol contributions), the transmittance of a 5.1 km path is 99%. A  $\pm 3\%$  value for  $dT/T$  translates into a 300% uncertainty in  $d\epsilon/\epsilon$ . The aerosol component required to produce agreement between the measured extinction coefficient and the calculated FASCODE water continuum absorption coefficient is typically 0.02 to  $0.03 \text{ km}^{-1}$  for the ASL and PRNAS spectra shown in Figures 12 and 13, and consequently overwhelms the small water vapor continuum absorption coefficients corresponding to these spectra. The relatively large amount of scatter in the data points between 2800 and  $3060 \text{ cm}^{-1}$  seen in the ASL spectra reflects the fact that the measured transmittances were very high, on the order of 80%. In this case  $d\epsilon/\epsilon = 4.5 \times dT/T$  or  $\pm 13.4\%$  for a value of  $dT/T = \pm 3\%$ . There is an indication, within the uncertainties identified above, that the experimental absorption coefficient values are usually larger than the calculated values in the region from  $2800 \text{ cm}^{-1}$  to  $2980 \text{ cm}^{-1}$  and frequently smaller than the calculated values for  $\nu > 3000 \text{ cm}^{-1}$ . The latter behavior is apparent in the PRNAS spectra collected for absolute humidities,  $\sim 5.5 \text{ torr ppH}_2\text{O}$ .

The SNI Spectra show generally good agreement with the FASCODE calculations in the spectral region between  $2600 \text{ cm}^{-1}$  and  $3000 \text{ cm}^{-1}$ . Due to the large variation in absorption coefficient between  $1970 \text{ cm}^{-1}$  and  $2200 \text{ cm}^{-1}$  the plots shown in Figures 14 (a) through 14 (e) are scaled such that the coefficient values between  $2400 \text{ cm}^{-1}$  and  $2900 \text{ cm}^{-1}$  are

difficult to discern. The tabular listings of the plotted values presented in appendix A are useful for obtaining quantitative comparisons in this spectral region.

A general feature of all of the SNI data except for the plots of spectra SNI02, SNI04, SNI05, and SNI06 is that the experimental data points between  $1974.10\text{ cm}^{-1}$  and  $2223.68\text{ cm}^{-1}$  lie below the calculated points as do the ASL spectral points in this region. The relatively large aerosol component and its associated uncertainty undoubtedly contribute to the inconsistencies seen in the SNI data.

In all of the comparisons of the SNI data shown in Figures 14 (a) through 14 (e) the data points between  $2959.87\text{ cm}^{-1}$  and  $3058.71\text{ cm}^{-1}$  exhibit larger extinction values than do the corresponding calculated points.

As previously discussed, the effects of uncertainties associated with the correction for local line contributions render the corrected values of the data points at  $2979.52\text{ cm}^{-1}$  questionable.

The CCAFS data shown in Figures 15(a) through 15(g) show rather consistent behavior in that the experimental extinction values are smaller than the calculated values between  $1930.30\text{ cm}^{-1}$  and  $2102.15\text{ cm}^{-1}$  and again between  $2880.80\text{ cm}^{-1}$  and  $3058.71\text{ cm}^{-1}$ . In general, the CCAFS data points fall on smoother curves than do the data from the other three data sets. This is in part due to the fact that the higher molecular absorption coefficients seen in the CCAFS data are larger than the fundamental experimental uncertainties in the measurements. The several data points subject to errors in the local-line-absorption corrections are quite obvious when examining the plots of the CCAFS data. A good comparison of the "shape" of the FASCODE water continuum absorption coefficient with that determined by the

experimental data is presented in the several plots of the CCAFS data shown in Figures 15(a) through 15(g).

The use of Nd-YAG laser transmittance measurements as an independent means of assessing the aerosol extinction component in the 3-5  $\mu\text{m}$  region was discussed in subsection 3.1.2.2. The CCAFS spectra for which Nd-YAG laser transmittance values are available are listed in Table 9 and include the spectra designated as CC144, -145, -147, -148, -153, -154, -157, -158, -159, -160, and -161. These spectra were re-plotted using infrared aerosol extinction coefficients at  $2700.72\text{ cm}^{-1}$  derived from the measured Nd-YAG extinction coefficients listed in Table 10. The humidity and wavelength scaling discussed in subsection 3.1.2.2 and the modeled wavelength dependence given by Equations 8 and 9 were used. Figures 16(a) through 16(e) show the results of using this approach to determine an experimental water vapor continuum absorption coefficient.

The comparison shown in Figure 16(a) between experimental data points for spectra CC144 and CC145 and calculated values for FASCODE case 9 shows a significant difference between the measured and calculated values. Over the spectral range from  $2501.00\text{ cm}^{-1}$  to  $2958.87\text{ cm}^{-1}$  the experimental data points for the two CCAFS spectra are essentially superimposed on one another and are larger than the corresponding calculated points by an amount varying from  $0.067\text{ km}^{-1}$  at  $2501.00\text{ cm}^{-1}$  to  $0.034\text{ km}^{-1}$  at  $2959.87\text{ cm}^{-1}$  (see Appendix A for a tabulation of the difference values).

The several comparisons shown in Figures 16(b) through 16(e) show generally close agreement between the magnitudes of the measured data and calculated values over the  $2599.84\text{ cm}^{-1}$  to  $2941.37\text{ cm}^{-1}$  region. In light of the distinctly different appearance of the comparison shown in Figure 16(a), it is likely that the relatively large differences in

extinction values are due to an incorrect determination of the aerosol component of the total extinction. The time differences between the FTS and calibrating DF laser measurements are comparable for the CC144 and CC145 spectra to those for the several succeeding spectra and the measured aerosol extinction coefficient at  $1.06\text{ }\mu\text{m}$  remained fairly constant during the FTS and DF laser measurement period. The discrepancy in evaluation of the aerosol component for the spectra shown in Figure 16(a) therefore cannot be readily explained on the basis of the above considerations.

The remaining data and comparisons shown in Figures 16(b) through 16(e) form a rather consistent data set. In all cases the measured values exceed the calculated values over the range between  $2400.00\text{ cm}^{-1}$  and  $2941.37\text{ cm}^{-1}$ . A crossover occurs between  $2920$  and  $2940\text{ cm}^{-1}$  and the experimental data are lower than the calculated values for wavenumbers larger than  $2940\text{ cm}^{-1}$ .

Looking at the comparisons in the longer wavelength region one sees good agreement in extinction magnitude for the data points between  $2130.50\text{ cm}^{-1}$  and  $2190.95\text{ cm}^{-1}$ . The measured extinction values are consistently smaller than the calculated values for wavenumbers smaller than  $2130.50\text{ cm}^{-1}$ . The ratio of the measured extinction values to those calculated using FASCODE for all of the data shown in Figures 12 through 16 is tabulated in Appendix A. These ratios can be used to determine the size of the correction factor needed to produce exact agreement between the measured data and the FASCODE result, keeping in mind that the validity of the correction factor so derived rests on the validity of the aerosol extinction corrections described above.

For purposes of quantitatively determining a correction factor for the FASCODE water vapor continuum absorption coefficient, the spectral values plotted in Figures 16 (b)

through 16 (e) were divided into two groups, corresponding to different ranges of absolute humidity. Data for spectra CC147, -148, -153, and -154, corresponding to the absolute humidity range between 16.3 and 17.4 torr  $\text{ppH}_2\text{O}$ , were averaged together as were those for spectra CC157, -158, -159, -160, and -161 which correspond to the water vapor partial pressures of 20.0 and 20.5 torr. The average values of the ratio of the measured data to the calculated values, CC/FCD, for each of the two groupings are plotted as two separate curves versus wavenumber in Figures 17(a) and 17(b).

In Figure 17(a), the measured values are seen to be about 55% of the calculated values at  $1980\text{ cm}^{-1}$ , rising to near unity around  $2060\text{ cm}^{-1}$ . The data points corresponding to the higher absolute humidities define a lower-valued curve nearly parallel to that for the lower humidity data. The two curves show small variations with wavenumber around the value of unity in the region between  $2060\text{ cm}^{-1}$  and  $2140\text{ cm}^{-1}$ . The error bars, shown only on one curve for simplicity, represent the RMS deviated from the average value calculated for each set of spectra. The RMS values are comparable in magnitude for each of the two curves shown in Figure 17(a).

The shorter wavelength data shown in Figure 17(b) show a considerably larger value for the CC/FCD ratio of about 2.4 at  $2400\text{ cm}^{-1}$ , dropping to a value of unity around  $2925\text{ cm}^{-1}$  and then to a value of 0.55 at  $3000\text{ cm}^{-1}$ . As in the case of the long wavelength region shown in Figure 17(a), the data for the two absolute humidity groupings define two nearly parallel curves, only with the higher humidity curve showing larger extinction values in this case.

The rapid increase of the value of the CC/FCD ratio for wavenumbers shorter than  $2700\text{ cm}^{-1}$  seen in Figure 17(b) can probably be attributed to inaccuracies in the calculated corrections for  $\text{CO}_2$  and  $\text{N}_2$  continuum contributions to the total extinction. An examination of the calculated  $\text{CO}_2$  and  $\text{N}_2$  continuum contributions tabulated in Appendix C shows that the  $\text{N}_2$  continuum contribution is important for wavenumbers between  $2084.35\text{ cm}^{-1}$  and  $2223.68\text{ cm}^{-1}$  on the long wavelength side of the  $\nu_3$   $\text{CO}_2$  band and for wavenumbers between  $2400.00\text{ cm}^{-1}$  and  $2740.74$  on the short wavelength side. Superimposed on the  $\text{N}_2$  continuum absorption coefficient is the  $\text{CO}_2$  band-wing continuum, important for wavenumbers between  $2400.00\text{ cm}^{-1}$  and about  $2520\text{ cm}^{-1}$ .

Thus, the initial sharp rise of the CC/FCD curves in Figure 17 for wavenumbers below  $2700\text{ cm}^{-1}$  likely can be attributed to an under-estimation of the  $\text{N}_2$  continuum absorption in the FASCODE model. For wavenumbers below about  $2520\text{ cm}^{-1}$  in Figure 17(b) the sum of the  $\text{CO}_2$  and  $\text{N}_2$  absorptions are underestimated. Since the  $\text{N}_2$  continuum appears to be underestimated in the region between  $2520\text{ cm}^{-1}$  and  $2720\text{ cm}^{-1}$ , and no abrupt discontinuity in the curves shown in Figure 17(b) is evident around  $2520\text{ cm}^{-1}$ , it is likely that the  $\text{N}_2$  continuum underestimate is the major contributor to the large values of the CC/FCD ratio seen in Figure 17(b) between  $2400\text{ cm}^{-1}$  and  $2720\text{ cm}^{-1}$ . The slopes of the curves in Figure 17(b) level out around  $2700\text{ cm}^{-1}$  (before turning down around  $2800\text{ cm}^{-1}$ ), at a value of about 1.25, indicating that the calculated FASCODE water vapor continuum absorption coefficient is about 77% of the average experimental values in this region.

For wavenumbers greater than about  $2925\text{ cm}^{-1}$  the CC/FCD ratio is less than unity in Figure 17(b) indicating that the model predicts anomalously high water vapor absorption in this region.

FIGURE 17a. RATIO OF MEASURED TO CALCULATED VALUES FOR WATER VAPOR CONTINUUM ABSORPTION COEFFICIENTS VERSUS WAVENUMBER, 1980 cm<sup>-1</sup> to 2140 cm<sup>-1</sup>.

FIGURE 17b. RATIO OF MEASURED TO CALCULATED VALUES FOR WATER VAPOR CONTINUUM ABSORPTION COEFFICIENTS VERSUS WAVENUMBER, 2400 cm<sup>-1</sup> to 3000 cm<sup>-1</sup>.

It is interesting to note also that the positive slope in the region of the curves shown in Figure 17(a) between  $2100\text{ cm}^{-1}$  and  $2160\text{ cm}^{-1}$  is consistent with the observation made with respect to Figure 17(b) that the predicted  $\text{N}_2$  continuum absorption coefficients are too large.

The comparisons shown in Figure 17(b) should not be interpreted as showing that the experimental water vapor continuum absorption coefficient is 2.4 times as large as the FASCODE-calculated result at  $2400\text{ cm}^{-1}$ . The point has already been made that the calculated  $\text{N}_2$  continuum absorption coefficient is too large and probably accounts for the discrepancies shown in Figure 17(b). The relative magnitudes of the calculated  $\text{H}_2\text{O}$  and  $\text{CO}_2 + \text{N}_2$  continuum absorption coefficients can be determined by an examination of the results tabulated in Appendices A and C respectively. Since the magnitude of the  $\text{CO}_2 + \text{N}_2$  continuum optical depths at  $2400\text{ cm}^{-1}$  is some 25 to 28 times larger than the calculated  $\text{H}_2\text{O}$  continuum absorption coefficients at that frequency (0.7 to 0.9 versus 0.025 to 0.035), the apparently large deviation from unity shown in Figure 17(b) must be kept in this context. The large deviations represent only a 10 - 12% change in the magnitude of the calculated  $\text{N}_2$  optical depth at  $2400\text{ cm}^{-1}$ .

The error bars plotted in Figures 17(a) and 17(b) show the RMS deviations from the average values for the CC/FCD ratios plotted for each group of spectra.

The uncertainties in the measured data associated with the ratios shown in Figures 17(a) and 17(b) can be determined by combining the experimental uncertainties in the measured data together with the uncertainties associated with the calculated local line contributions and estimated aerosol extinction corrections.

The experimental uncertainty in the measured transmittance is accepted to be  $\pm 3\%$  in most cases and in all of the cases shown in Figures 17(a) and 17(b). Typically the maximum average transmittance values in the spectral range shown in the figures is about 80%. Referring to Equation 10 we see that the resultant uncertainty in measured optical depth corresponding to a  $\pm 3\%$  transmittance uncertainty is  $\pm 13.5\%$ .

The calculated local line contributions to the total optical depth can be seen to range from low values of 0.3 to 0.4 of the FASCODE-calculated  $H_2O$  continuum absorption values to higher values which are 20 to 150 times as large as the  $H_2O$  continuum values, depending upon the particular wavenumber locations under consideration. Since the comparison plots shown in Figures 12-16 show generally smooth behavior as a function of wavenumber for a wide variation in local-line-correction values to the optical depth, (see Appendix B), it may be concluded that the magnitudes of the calculated corrections are generally quite good, except for the specific wavenumber previously noted. Assuming a conservative estimate of a  $\pm 20\%$  uncertainty in the calculated local line contributions in the  $2500 - 2900 \text{ cm}^{-1}$  region, and noting that the magnitude of these corrections is 30-40% of the  $H_2O$  continuum absorption values in this region, then an estimate of the uncertainties in the comparisons shown in Figures 17(a) and 17(b) due to uncertainties in local line absorption coefficients would be  $\pm 8\%$ .

The uncertainties in the CC/FCD ratios due to corrections for aerosol attenuation are difficult to estimate. The measured Nd-YAG transmittance values can be characterized by a  $\pm 3\%$  uncertainty, just as the measured DF laser transmittances. However, the uncertainty associated

with the extrapolation of aerosol extinction values measured at  $1.06\text{ }\mu\text{m}$  to  $3.8\text{ }\mu\text{m}$  is difficult to ascertain in a quantitative manner. If one assumes that on the average this extrapolation has associated with it a  $\pm 25\%$  uncertainty, then the Nd-YAG transmittance-derived aerosol extinction corrections at  $3.8\text{ }\mu\text{m}$  would have an uncertainty of  $\pm 20\%$ .

Combining the three categories of contributing uncertainties, the measured (and appropriately corrected) data used in the comparisons shown in Figures 17(a) and 17(b) would have associated with them an overall uncertainty of  $\pm 55\%$ . This value easily includes the FASCODE-derived  $\text{H}_2\text{O}$  continuum absorption prediction in the  $2500 - 2900\text{ cm}^{-1}$  region. The large deviation due to  $\text{N}_2$  continuum absorption near  $2400\text{ cm}^{-1}$  must be viewed independently from the  $\text{H}_2\text{O}$  continuum comparisons as previously discussed.

### **3.2 WATER VAPOR LINE ABSORPTION ANALYSIS**

#### **3.2.1 SURVEY COMPARISONS BETWEEN MEASUREMENTS AND CALCULATIONS**

This section presents a comparison between two of the measured spectra and FASCODE calculations over the full spectral range of the measurements from  $1900\text{ cm}^{-1}$  to  $3200\text{ cm}^{-1}$ . The two spectra chosen were selected to be representative of low and high water vapor amounts and to have high signal to noise and visibility: spectrum ASL06 corresponds to  $2.9\text{ gm cm}^{-2}$  of water vapor along the path with 100 km visibility and spectrum CC159 corresponds to  $10.3\text{ gm cm}^{-2}$  of water vapor with 35 km visibility. The calculated spectra were produced using FASCOD1C and the 1982 version of the AFGL Line Tape.

Figure 18 shows a low resolution comparison between one of the measured spectra (ASL06) and the FASCODE calcula-

FIGURE 18. SPECTRUM ASL06, 1900-3200  $\text{cm}^{-1}$ , DEGRADED WITH A 10  $\text{cm}^{-1}$  HWHM TRIANGULAR INSTRUMENT FUNCTION, MEASURED (SOLID) AND FASCODE (DASHED), NO AEROSOL ATTENUATION IS INCLUDED IN THE FASCODE CALCULATION.

tion; both the measured and the calculated spectra have been degraded with a  $10 \text{ cm}^{-1}$  half-width at half-height triangular instrument function. By degrading the spectra it is possible to survey the whole range from  $1900$  to  $3200 \text{ cm}^{-1}$  on a single plot. No aerosol extinction has been included in the FASCODE calculation so that the calculated transmittance in the windows is generally higher than the measured transmittance.

Figures 19 and 20 show the high resolution comparisons for each of the measured spectra in sections of  $100 \text{ cm}^{-1}$  each. In these comparisons the following points should be noted:

1. No aerosol extinction is included in the calculation.
2. The resolution of the measurement is determined by the instrument function which is a sinc function:  $\sin(2\pi\nu L)/(2\pi\nu L)$  where the optical retardation  $L = 16 \text{ cm}$ . The half width at half-height of this function is  $0.018 \text{ cm}^{-1}$ . The half widths of atmospheric absorption lines are typically  $0.08 \text{ cm}^{-1}$  but may be as small as  $0.009$  for some anomalously narrow water lines. Therefore, for most of the absorption lines in this spectra, the absorption at the line center will not be greatly reduced by the limited instrument resolution: for the narrow water lines however, the effect may be large.
3. In the measured spectrum ASL06, zero percent transmittance level in the measurement is displaced by about  $0.05$  at  $1900 \text{ cm}^{-1}$  decreasing to a negligible value at  $2260 \text{ cm}^{-1}$ . There appears to be no displacement at  $2390 \text{ cm}^{-1}$  and above  $2900 \text{ cm}^{-1}$ . The non zero transmittance seen between  $2330 \text{ cm}^{-1}$  and  $2390 \text{ cm}^{-1}$  is not real but is an artifact of the calibration procedure.
4. There are a number of apparent "mini-windows" in the measured spectrum ASL06 between  $1900 \text{ cm}^{-1}$  and  $2000 \text{ cm}^{-1}$  which are not seen in the

calculation, for example, at  $1917\text{ cm}^{-1}$  and  $1942\text{ cm}^{-1}$ . These features are apparently not real : they are not seen in other high resolution atmospheric spectra under similar conditions, for example, Figure 21, shows a spectrum which was taken at Kitt Peak [18]. This measurement was made at a resolution of about  $0.02\text{ cm}^{-1}$  and contains about the same amount of total air in the path as spectrum ASL06 (about 1 air mass) but much less water vapor. These artifacts are also not seen in the measured spectra CC154.

The exact cause of the artifacts is not known. However the positions of these features correspond one-to-one with the positions of strong water vapor lines listed on the AFGL Line Tape. One possible explanation for these features is that they are somehow generated in the calibration procedure when ratioing a long path spectrum to a "zero path" one. Here the source and receiver optical system were separated by about 30 meters. The transmittance measured over this short path is used to normalize the long path transmittance. Strong absorption by these lines over the short path could generate these features in the normalized spectra due to lack of numerical precision in the ratioing of two small numbers which is performed in the normalization procedure.

### **3.2.2 ESTIMATES OF LINE STRENGTHS FOR WATER VAPOR ABSORPTION LINES IN THE $2390\text{ cm}^{-1}$ TO $2500\text{ cm}^{-1}$ SPECTRAL REGION**

There are a number of molecular absorption lines of water vapor between  $2390\text{ cm}^{-1}$  to  $2500\text{ cm}^{-1}$  whose strengths in the 1982 edition of the AFGL Atmospheric Absorption Line Parameter Compilation [9] are too large. These lines are seen marked by arrows in Figure 22, which is a comparison between the measured spectra CC154 and a FASCODE calculation using the 1982 version of the AFGL Line Compilation. The lines due to water vapor are marked by arrows. Some of these lines stand out clearly in the calculated spectrum but

FIGURE 21. ATMOSPHERIC ABSORPTION SPECTRUM FOR 1900-1950  $\text{cm}^{-1}$  MEASURED AT KITT PEAK OBSERVATORY; MEASUREMENT CONDITIONS INCLUDE 0.02  $\text{cm}^{-1}$  RESOLUTION, 1.1 AIP-MASS PATH, 0.8  $\text{g/m cm}^2$  WATER VAPOR ALONG THE PATH; TAKEN FROM [18].

FIGURE 22. MEASURED SPECTRUM CCl<sub>4</sub> (BOTTOM), AND FASCODE (TOP) CALCULATION.  
ARROWS POINT TO WATER VAPOR LINES.

are much weaker or completely absent in the measurement. Figure 23 shows separately the  $1\text{ cm}^{-1}$  region around each of the marked lines and include the measured spectrum CC154 and FASCODE calculations using both the 1982 version of the AFGL Line Compilation (solid line) and the 1980 version (dashed line). There are several points which can be made concerning these comparisons:

1. The calculations are monochromatic while the measurement includes the effect of a sinc instrument function with a half width at half height of  $0.018\text{ cm}^{-1}$ . The widths of some of these water lines are as small as  $0.01\text{ cm}^{-1}$  so that these narrow lines are somewhat degraded in the measured spectra.
2. Due to the lack of aerosol extinction in the calculation, the measured lines ride on lower background transmittances than the calculation, so that even if the calculated lines were of the proper strength, the calculated lines would appear deeper (in transmittance) than the measured.
3. The strengths for these lines were revised for the 1980 version of the AFGL Line Compilation. In most cases the strengths were increased. When it was realized that these revised strengths were too large compared to measurements, the earlier line strength values from the 1978 compilation were used again for the 1982 compilation.
4. There is a small systematic error in the wave-number scale of the measured spectrum as determined by comparison with accurately known  $\text{N}_2\text{O}$  lines around  $2450\text{ cm}^{-1}$ . This error has been corrected in the plots as shown in Figure 22.

From the plots in Figure 22 it is possible to estimate the strength of the measured lines relative to the calculated values. This was done by comparing the depths of the absorption line at the line center relative to the local background between the measured and the calculated lines

FIGURE 23. MEASURED SPECTRUM CC154 (SYMBOLS) AND FASCODE CALCULATION WITH AFGL LINE TAPE, 1982 VERSION (SOLID LINE) AND 1980 VERSION (DASHED LINE). ARROW POINTS TO CENTER OF WATER VAPOR LINE.

FIGURE 23. (CONTINUED).

using the 1982 version of the AFGL compilation. The effect of the different background transmittance levels was accounted for but the effect of the finite resolution of the measurement was not. In many cases the absorption line is not discernible in the measurement above the noise. In these cases, the depth of the measured line was taken to be equal to the level of the noise, as estimated from the plots (about  $\pm 0.01$  transmittance) and only an upper limit for the strength of these lines is given.

The results of this analysis are given in Table 12 which lists for each absorption line, the frequency of the line center, the strength, the halfwidth, and the upper and lower vibrational and rotational quantum numbers, all taken from the 1982 version of the AFGL Line Compilation [9]. The last column, labeled R, is the ratio of the measured line strength to the value in the AFGL line compilation. Values of R which represent an upper limit are indicated by <. Estimates of some of the values are uncertain due to interfering lines of other molecules; these values are indicated with an asterisk. Estimates for the remaining values are uncertain by  $\pm 10$  percent, based on comparisons performed for lines whose strengths are well known.

Note that the lines for which R is significantly different from 1.0 belong to the band (010,000): the measured strengths for the band (001,010) all agree with the AFGL values within the experimental uncertainty. The AFGL strengths were calculated based on observations of strong lines from the (010,000) band. The extrapolation of the calculation to the weaker lines involves large uncertainties, especially for values of  $\Delta K_a = 3$  or 5 [19].

## CONCLUSIONS AND RECOMMENDATIONS

### 4.1 CONCLUSIONS

The conclusions which have been reached as a result of this study can be summarized as follows:

1. The several sets of spectra described in Section 2.2 have been shown to be accurate to  $\pm 3\%$  in absolute transmission, based on the established accuracy of the DF laser transmittance measurements used to provide the absolute transmittance calibrations for each spectrum. The RMS deviations from the hypothetical, ideal multiplicative scale factor of unity which characterize the accuracy of the absolute transmittance normalization procedure over the range of DF laser measurements used to normalize a particular spectrum has been shown to be within 4% in absolute transmission units in all but a few isolated cases. In most cases the RMS deviations is less than 2%. The normalized spectra typically differs from unity by less than 1%. See Section 2.2 for a discussion of these results which are tabulated in Tables 1, 3, 4, and 5.

2. The CCAFS results have been found to be most useful for the purposes of the present study for two reasons, namely:

a) these data correspond to a wider range of atmospheric humidity conditions than do the other data and include measurements under higher absolute humidities than do the other data sets. The resolution of questions concerning water vapor continuum absorption (treated in Section 3.1.4) is best addressed using several of the CCAFS spectra measured during high visibility (low aerosol extinction), high water vapor conditions, and

b) during several of the CCAFS measurements, laser transmittance measurements using a Nd-YAG laser operating at  $1.06 \mu\text{m}$  were performed. The results of these measurements, scaled to  $3.7 \mu\text{m}$  are considered a more reliable measure of aerosol extinction at  $3.7 \mu\text{m}$  than concurrent, land-based (and surf-influenced) aerosol particulate

spectrometer data or than estimates derived from maritime aerosol extinction models. (See Section 3.1.2.2).

3. Determination of the aerosol extinction contributions to the total measured extinction probably represents the largest source of uncertainty in the analysis of the data. Various approaches were evaluated depending upon the amount of independent information available for each data set. Only visibility data (supplied by the NAVCOM, PRNAS) were available for the PRNAS data. Independent Nd-YAG laser transmissometer data were available for some of the CCAFS data and provide the most useful means of determining the value of aerosol extinction at  $3.7 \mu\text{m}$ .

4. Using the semi-empirical procedure of determining the aerosol extinction component at  $3.7 \mu\text{m}$  by subtracting the FASCODE-calculated molecular absorption coefficient from the measured total extinction coefficient (actually optical depth), the shape of the envelope of the measured optical depth as a function of wavenumber (corrected for  $\text{N}_2$  and  $\text{CO}_2$  continua, and local line effects) was compared with the equivalent FASCODE calculation. In nearly all cases (see Figures 12 through 15) the measured data show a smaller optical depth relative to the calculations for  $1979 \text{ cm}^{-1} < \nu < 2177 \text{ cm}^{-1}$  and again for  $\nu > 2920 \text{ cm}^{-1}$ . For  $2400 \text{ cm}^{-1} < \nu < 2650 \text{ cm}^{-1}$  the measured optical depths are larger than the calculated values. The former comparisons are interpreted as indicating differences between the predicted and measured  $\text{H}_2\text{O}$  continuum absorption contribution. The latter comparisons (in the  $2400\text{--}2650 \text{ cm}^{-1}$  range) are interpreted as pointing up a discrepancy between the calculated  $\text{N}_2$  continuum absorption coefficient and the measured values.

5. The FASCODE-generated water vapor continuum optical depth is seen to agree with the experimental data in the  $2600 \text{ cm}^{-1}$  to  $2800 \text{ cm}^{-1}$  range to within the range of

uncertainty of the data, conservatively estimated to be  $\pm 55\%$ . See section 3.1.4 for a discussion of the estimated experimental uncertainty.

6. The high-resolution survey comparisons shown in Figures 19 and 20 point-out certain discrepancies between the measured and calculated high resolution spectra in each of the cases compared. In spectrum ASL06, shown in Figure 19(a) through 19(m) certain features appear in the measured data in the region between  $1900\text{ cm}^{-1}$  and  $2000\text{ cm}^{-1}$ . These features do not appear in the calculation. Since these features do not appear in the CC159 spectrum or in the high resolution Kitt Peak spectrum shown in Figure 21, they therefore must represent artifacts introduced in the measurement and/or data reduction processes. Since their location corresponds to the location of strong water vapor absorption lines, the most likely explanation involves the lack of sufficient dynamic range in the computations used in the numerical ratio of the long path spectrum to its zero-path-counterpart.

It can also be seen that the FASCODE calculation shows generally lower transmission than the measurement in this region ( $1900\text{--}2000\text{ cm}^{-1}$ ). Although no aerosol attenuation has been included in the calculation, making a one-to-one comparison of the measured and calculated transmission values invalid, the amount of aerosol extinction that would realistically correspond to the measurement conditions (100 km visibility corresponding to  $\sim 0.003\text{ km}^{-1}$  aerosol attenuation at  $3.8\text{ }\mu\text{m}$ ) is quite small and should not substantially alter the comparison shown in Figure 19(a).

7. The line-strengths of several of the weak water vapor absorption lines occurring between  $2390\text{ cm}^{-1}$  and  $2490\text{ cm}^{-1}$  are seen to be overestimated in the current AFGL atmospheric absorption line compilation. As demonstrated in Section 3.2.2 the 1982 version of the line compilation is in better agreement with experimental observations than are the data

included in the 1980 version. The results of comparisons of the experimental data to calculations performed using the 1982 version of the line compilation are summarized in the Table 12 and show that the measured line strengths vary from 0.02 to 1.2 times the values predicted using the 1982 compilation. On the average the observed values are in the range of about 10 to 30% of the predicted values.

#### 4.2 RECOMMENDATIONS

Certain recommendations can be made as a consequence of the comparisons and analyses performed during the present study. These recommendations include the following:

1. More extensive quantitative comparisons of the high-resolution FTS data treated in this study might be developed if the aerosol extinction component at  $3.7\mu\text{m}$  in the various spectra can be determined unequivocally. Use of the comparisons shown in Figures 12-15 as a basis to establish a "zero-order" aerosol extinction coefficient, combined with the use of aerosol model predictions in a self-consistent analysis is recommended. The somewhat detailed statistical analysis that would be required was not possible within the scope of the present study. If this recommendation were to be implemented, the water vapor dependence of the  $3\text{-}5\mu\text{m}$  water vapor continuum absorption could be examined in greater detail.

2. A further investigation of the apparent excess  $\text{N}_2$  continuum absorption evidenced in the comparisons shown in section 3.1.3.4 should be performed. The suggestion has been made [20] that an unaccounted for temperature dependence of the  $\text{N}_2$  continuum absorption may be responsible for the discrepancies between the calculated and measured results shown in Figure 17. This question should be further investigated using the data treated in this study as well as pertinent laboratory data.

3. The line strengths of several of the weak water vapor absorption lines occurring between  $2390\text{ cm}^{-1}$  and  $2490\text{ cm}^{-1}$  are clearly too large as they appear in the 1982 AFGL atmospheric absorption line compilation. The line strength values for these lines should be modified on future editions of the compilation to reflect the values tabulated in Table 12.

4. The analysis performed in the present study has shown certain of the CCAFS spectra to be the most useful in comparisons of calculated and measured values for the weak,  $3\text{-}5\text{ }\mu\text{m}$  water vapor absorption coefficient. These are the spectra collected during high humidity, high visibility conditions. Atmospheric conditions corresponding to substantially greater absolute humidities than the 20 torr  $\text{ppH}_2\text{O}$  corresponding to several of the CCAFS spectra are unlikely to occur at any experimental site. The only remaining alternative to increasing the total path-integral amount of water vapor in an experimental configuration is the use of a longer measurement path-length. The use of larger collecting apertures ( $\sim 1.2\text{ m}$ ) which can provide complete collection of a laser transmissometer beam under conditions of moderate atmospheric turbulence over paths lengths of  $10\text{-}50\text{ km}$  is currently under study. Data similar to those discussed in the present study but collected over much longer paths (provided that aerosol attenuation remains small and/or usefully characterized) should provide information which can be used to reduce the quantitative uncertainties which persist as a result of the present analysis.
